Abstract

Background
Adult smoking usually has its roots in adolescence. If individuals do not take up smoking during this period it is unlikely that they ever will. Further, once smoking becomes established, cessation is challenging; the probability of subsequently quitting is inversely proportional to the age of initiation. One novel approach to reducing the prevalence of youth smoking is the use of incentives.

Objectives
To determine whether incentives prevent children and adolescents from starting to smoke. We also attempted to assess the dose-response of incentives, the costs of incentive programmes, whether incentives are more or less effective in combination with other interventions to prevent smoking initiation and any unintended consequences arising from the use of incentives.

Search methods
We searched the Cochrane Tobacco Addiction Group Specialized Register, with additional searches of MEDLINE, EMBASE, CINAHL, CSA databases and PsycINFO for terms relating to incentives, in combination with terms for smoking and tobacco use, and children and adolescents. The most recent searches were in May 2012.

Selection criteria
We considered randomized controlled trials allocating children and adolescents (aged 5 to 18 years) as individuals, groups or communities to intervention or control conditions, where the intervention included an incentive aimed at preventing smoking uptake. We also considered controlled trials with baseline measures and post-intervention outcomes.

Data collection and analysis
Data were extracted by two authors and assessed independently. The primary outcome was the smoking status of children or adolescents at follow-up who reported no smoking at baseline. We required a minimum follow-up of six months from baseline and assessed each included study for risk of bias. We used the most rigorous definition of abstinence in each trial; we did not require biochemical validation of self-reported tobacco use for study inclusion. Where possible we combined eligible studies to calculate pooled estimates at the longest follow-up using the Mantel-Haenszel fixed-effect method, grouping studies by study design.
Main results

We identified seven controlled studies that met our inclusion criteria, including participants with an age range of 11 to 14 years. Of the seven trials identified, only five had analysable data relevant for this review and contributed to the meta-analysis (6362 participants in total who were non-smokers at baseline; 3466 in intervention and 2896 in control). All but one of the studies was a trial of the so-called Smokefree Class Competition (SFC), which has been widely implemented throughout Europe. In this competition, classes with youth generally between the ages of 11 to 14 years commit to being smoke free for a six month period. They report regularly on their smoking status; if 90% or more of the class is non-smoking at the end of the six months, the class goes into a competition to win prizes. The one study that was not a trial of the SFC was a controlled trial in which schools in two communities were assigned to the intervention, with schools in a third community acting as controls. Students in the intervention community with lower smoking rates at the end of the project (one school year) received rewards.

Only one study of the SFC competition, a non-randomized controlled trial, reported a significant effect of the competition on the prevention of smoking at the longest follow-up. However, this study had a risk of multiple biases, and when we calculated the adjusted RR we no longer detected a statistically significant difference. The pooled RR for the more robust RCTs (3 studies, n = 3056 participants) suggests that, from the available data, there is no statistically significant effect of incentives to prevent smoking initiation among children and adolescents in the long term (RR 1.00, 95% CI 0.84 to 1.19). Pooled results from non-randomized trials also did not detect a significant effect, and we were unable to extract data on our outcome of interest for the one trial that did not study the SFC. There is little robust evidence to suggest that unintended consequences (such as youth making false claims about their smoking status and bullying of smoking students) are consistently associated with such interventions, although this has not been the focus of much research. There was insufficient information to assess the dose-response relationship or to report costs.

Authors’ conclusions

To date, incentive programmes have not been shown to prevent smoking initiation among youth, although there are relatively few published studies and these are of variable quality. Trials included in this meta-analysis were all studies of the SFC competition, which distributed small to moderately sized prizes to whole classes, usually through a lottery system.

Future studies might investigate the efficacy of incentives given to individual participants to prevent smoking uptake. Future research should consider the efficacy of incentives on smoking initiation, as well as progression of smoking, evaluate these in varying populations from different socioeconomic and ethnic backgrounds, and describe the intervention components in detail.

Plain Language Summary

Do incentives help keep young people from starting to smoke in the medium to long term?

Most smokers start smoking before they are 18 years old. Starting smoking earlier in life means a smoker will smoke for more years than someone who starts smoking later, which increases the associated health risks of smoking. Given the high amount of tobacco use among young people and the corresponding poor health outcomes this will result in in the future, strategies to prevent smoking in adolescence are a public health priority. One new approach to preventing young people from starting to smoke is the use of incentives, whereby young people or groups of young people are rewarded for being smoke free. The aim of this review was to assess the effect of incentives on preventing children and adolescents (aged 5 to 18 years) from starting to smoke.

This review included seven trials, six of which were trials of the so-called Smokefree Class Competition (SFC), which has been widely used throughout Europe. In this competition, classes with youth generally between the ages of 11 to 14 years commit to being smoke free for a six month period. They report regularly on their smoking status, and if 90% or more of the class is non-smoking at the end of the six months, the class goes into a competition to win prizes. We combined results from five trials of SFC and found that the competition did not have a significant impact on whether or not young people who were previously non-smokers started smoking. In the one trial that was not of the SFC, classes with the smallest percentage of students smoking at the school year’s end were given rewards, but we did not have enough information available to evaluate whether this programme was effective in preventing young people from starting to smoke.

Currently, there is no high quality evidence that incentives prevent young people from starting to smoke in the long term. Specifically, incentives associated with the SFC competition have not been shown to prevent young people from starting to smoke in the medium to long term, although there are relatively few published studies and these are of variable quality. Though potential negative effects
of the SFC competition have not been widely researched, the data that is available suggests that the SFC competition does not have significant negative effects.

**BACKGROUND**

**Description of the condition**

In 2004, 12% of all deaths among adults aged 30 years and over were attributable to tobacco use, equating to more than five million people a year (WHO 2012). Global projections of mortality data estimate that unless urgent action is taken on tobacco control, total tobacco-attributable deaths will increase to over 8 million in 2030 (Mathers 2006).

Data from the Global Youth Tobacco Survey (2000 to 2007) revealed that approximately 10% of students aged 13 to 15 years smoked cigarettes, with prevalence ranging from 5% in the Eastern Mediterranean to 19% in the European Region (Warren 2008). In the United States, surveillance data from 2010 to 2011 found that 18.1% of high school students (grades 9 to 12) had smoked cigarettes during the 30 days before the survey. The prevalence of current cigarette use was higher among male (19.9%) than female (16.1%) students (Eaton 2012).

Adult smoking usually has its roots in adolescence. If individuals do not take up smoking during this period it is unlikely that they ever will (Mayhew 2000). Moreover, once smoking becomes established, cessation is challenging; the probability of subsequently quitting is inversely proportional to the age of initiation (Breslau 1996). Unfortunately, most smokers initiate the behaviour before 18 years of age; indeed among those who smoke cigarettes, nearly 25% of young people have reported smoking their first cigarette before the age of ten years (GYTS 2002).

Earlier onset of smoking provides for more life-years of tobacco use, thereby increasing the associated health risks, including respiratory conditions, cardiovascular disease and cancers (USDHHS 2012). Earlier onset is also associated with heavier use and heavier tobacco users are less likely to quit smoking and therefore more likely to experience tobacco-related health problems (Breslau 1996).

Given the prevalence of tobacco use among young people and the corresponding health burden into the future, strategies to prevent smoking in adolescence are a public health priority. Currently, public health policies and programmes aimed at reducing tobacco use among adolescents have demonstrated varying levels of success. Tax increases on tobacco products have been found to be successful in reducing smoking among this target group (USDHHS 2012) and there is evidence for the effectiveness of mass media campaigns (Brinn 2010, USDHHS 2012). The evidence for the long term effectiveness of community and school-based programmes reported in the literature has been inconsistent over the years. However, the most recent US Surgeon General’s report (USDHHS 2012) suggests that coordinated, multi-component community programmes may be able to reduce smoking among young people; the mix of strategies and the reach of the programme are likely to affect results. Similarly, selected school-based smoking prevention programmes have demonstrated successful long term outcomes. Successful programmes are generally intensive, comprehensive, interactive, start early and are sustained, and are integrated into a community-level approach (USDHHS 2012).

One novel approach to reducing the prevalence of smoking is the use of incentives. An incentive may be defined as “any tangible benefit externally provided with the explicit intention of promoting positive health, educational or social behavioural change” (Kavanagh 2011, p.193). There is growing interest in the use of incentives schemes to encourage young people to adopt healthy and pro-social behaviours (Kavanagh 2011). A review of incentives programmes to improve health, education and other social behaviours in youth aged 11 to 19 years identified nine studies which focused on healthy behaviours (Kavanagh 2011). A meta-analysis of these studies found a statistically significant positive impact, although the number of studies was small, as were some of the sample sizes. Three studies in this review were anti-smoking interventions; a meta-analysis of two of the three studies showed a statistically significant effect of anti-smoking competitions on daily smoking rates at one year follow-up (RR 1.05, 95% CI 1.02 to 1.08). The efficacy of anti-smoking competitions for preventing smoking initiation was not reported.

**Description of the intervention**

Incentives may take the form of contests, competitions, incentive schemes, lotteries, raffles, and contingent payments. This range of incentives has been more extensively reviewed for its effectiveness for encouraging cessation and continued abstinence in smoking cessation programmes.

A Cochrane review of ‘Quit and Win’ contests found they delivered quit rates above baseline community rates, however the population impact appeared relatively low (Cahill 2008). A separate Cochrane review of the use of competitions and incentives for smoking cessation found no evidence for the effectiveness of
these interventions to enhance long-term abstinence from smoking, with any early success usually dissipating when the reward was no longer on offer (Cahill 2011). The authors of both reviews noted that the lack of high quality trials limited their conclusions and, in the case of Cahill 2011, most incentives in the included studies were small. However, a recent well-executed study of large financial incentives (up to $750) to employees of a multinational company based in the United States found smoking cessation in the incentive groups was significantly greater than in the control group and was sustained six months after the final payment (Volpp 2009).

Incentives schemes have also been used for managing chronic conditions, avoiding sexually transmitted infections and for weight loss and have been used in education (Marteau 2009). Systematic reviews of the wider literature relating to incentives for encouraging healthy behaviours have found that incentives are effective in stimulating ‘simple,’ discrete behavioural changes (e.g. clinic attendance) (Jochelson 2007; Kane 2004). Incentives aimed at more complex lifestyle behaviours (e.g. smoking and sexual behaviour) have been found to be successful in increasing participation in health promotion programmes but once the incentive is ceased, participants tend to revert to former behaviours (Jochelson 2007). It has also been argued that the size of the incentive is important, with higher-value incentives more powerful in encouraging behaviour change and participation in lifestyle programmes (Jochelson 2007).

How the intervention might work

Incentives operate on learning theory principles by giving an immediate reward for behaviours that will provide health gains in the future. In the field of behavioural economics, research has found that people are motivated by the experience of past rewards and the prospect of future awards (Camerer 1999). Moreover, the desire to avoid regret (i.e. not being rewarded) can be a strong force in decision making under risk (Connolly 2006). Incentive schemes are also framed around what is termed “present bias,” a tendency of humans to pursue immediate rewards ahead of rewards that are distant but more highly valued (Volpp 2008). Marteau et al. (Marteau 2009) highlight some unintended consequences of incentives, including the undermining of a participant’s intrinsic motivation (Kane 2004) and informed consent, as well as the potential for damaging the trust between health professionals and their patients.

Why it is important to do this review

While there is currently limited high quality evidence to support the use of incentives for smoking cessation, the two Cochrane reviews performed to date only included studies which targeted adults with the express aim of increasing quit rates. It is conceivable that incentives may be more successful with a young target group, who may be more sensitive to monetary rewards, and who might find it easier to not start smoking compared to the more complex task of quitting once dependent on nicotine. While there is promising evidence that incentives for youth might work, currently we do not know whether rewards are effective in preventing youth from starting to smoke. Given the magnitude of the problem globally, this is an area worthy of further investigation.

OBJECTIVES

To assess the effect of incentives on preventing children and adolescents (aged 5 to 18 years) from starting to smoke. Our review aimed to address the following questions:

1. Do incentives prevent children and adolescents from starting to smoke?
2. Does the amount and type of incentive affect prevention of smoking initiation?
3. What are the cost implications to the community of incentives?
4. Are incentives more or less effective in combination with other interventions to prevent smoking initiation?
5. What are the unintended consequences arising from the use of incentives (e.g. false claims, ineligible applicants)?

METHODS

Criteria for considering studies for this review

Types of studies

Randomized controlled trials allocating individuals, groups or communities to intervention or control conditions. Controlled trials with baseline measures and post-intervention outcomes. We included non-randomized controlled trials in this review as this is a new and novel area of research. We recognise that potential biases are likely to be greater for non-randomized studies compared with randomized trials (Higgins 2011). Therefore, a meta-analysis was conducted separately for randomized and non-randomized studies.
Types of participants
Children (aged 5 to 12 years) and adolescents (aged 13 to 18) in any setting. Our population of interest were baseline non-smokers as we were interested in the efficacy of incentives in preventing smoking initiation. We used the definition of non-smoker as provided in each study. We did not include trials aimed exclusively at pregnant women, since they are covered by a separate review (Lumley 2009).

Types of interventions
We adapted the definition of ‘incentive’ provided by Kavanagh 2011. Our definition of an incentive was any tangible benefit externally provided with the explicit intention of preventing smoking. This includes contests, competitions, incentive schemes, lotteries, raffles, and contingent payments to reward not starting to smoke. We included rewards to third parties (e.g. to schools, health-care providers or family members), as well as interventions that directly reward children and adolescents. For each study, we attempted to determine whether the participants received any other smoking interventions such as smoking education in school, and whether the control group received any interventions.

Types of outcome measures

Primary outcomes
The primary outcome was the smoking status at longest follow-up of children or adolescents who reported no smoking at baseline. We excluded controlled studies where repeated cross-sectional observations of participants were made before and after the intervention, as these did not provide data on our outcome of interest (the smoking status of the children or adolescents who reported no smoking at baseline). While the gold standard for this review was biochemically verified sustained abstinence from smoking, we used the outcomes defined by the included trials and have included trials that did not use biochemically verified outcomes. We have reported smoking status at the longest follow-up, with a minimum follow-up of six months from baseline (the start of the intervention).

Secondary outcomes
We aimed to assess the dose-response of the amount of incentive but there were insufficient data with which to do so. Where applicable, we report on the costs and any unintended harms from the use of incentives.

Search methods for identification of studies

Electronic searches
We conducted our final searches in May 2012. We searched the Cochrane Tobacco Addiction Group Specialized Register, which includes studies identified by systematic electronic searches of multiple databases, and handsearching of specialist journals and the ‘grey’ literature (conference proceedings and unpublished reports not normally covered by most electronic databases). At the time of the Register search it included reports of controlled trials identified from the Cochrane Central Register of Controlled Trials (CENTRAL) to Issue 5, 2012, from MEDLINE to April week 3 2012, from EMBASE to week 201218, and from PsycINFO to update 20120430. See the Tobacco Addiction Group Module in the Cochrane Library for full search strategies and a list of other resources searched, and see Appendix 1 for the strategy used to search the Register.

We undertook additional searches of the following databases: MEDLINE (Appendix 2, 1947 to 24th May 2012); EMBASE (Appendix 3, 1980 to 2012 week 20); CINAHL (Appendix 4, 1937 to 24th May 2012); PsycINFO (Appendix 5, 1806 to 24th May 2012); CSA (Appendix 6, search date 24th May 2012, ASSIA from 1987, ERIC from 1986, PAIS from 1972, Sociological Abstract from 1952).

Searching other resources
We checked cited studies while reviewing trial reports, and attempted to contact trial authors for any required unpublished data. We also searched across multiple registers in Current Controlled Trials (http://www.controlled-trials.com/) and in the Australian and New Zealand Trials Registry (http://www.anzctr.org.au/trialSearch.aspx) using all key word combinations for study protocols of completed and ongoing trials. We did not apply any language restrictions.

Data collection and analysis
There were three stages in the data collection and analysis process, outlined below.

Stage 1: Selection of studies
One reviewer (VJ) prescreened all studies identified in the electronic search for possible inclusion. Articles were rejected at this stage if the title and/or abstract did not focus on the impact of incentives on youth smoking behavior. If the article could not be categorically rejected by one reviewer on the basis of title and abstract, the full text was obtained and screened by two reviewers (VJ and DT).
Two reviewers independently assessed the relevant studies for inclusion. Discrepancies were resolved by consensus and we have reported reasons for the non-inclusion of studies (these appear in the Table of Excluded Studies). While we planned for the Cochrane Tobacco Addiction Group editorial team to resolve any ongoing disagreements between the two reviewers, this was not necessary during this review.

**Stage 2: Data extraction and assessment of risk of bias**

Two reviewers (VJ and DT) independently extracted the following data into a data extraction form. This form was piloted on a small sample of records and some minor modifications were made.

1. Study design, including inclusion and exclusion criteria, method of randomization (if used)
2. Setting (e.g. country, multi-centre or single centre, inpatient or outpatient etc.)
3. Demographics of participants, including average age, sex, socioeconomic status, smoking status
4. Intervention and control description
5. Primary outcome measure, including definition of abstinence and length of follow-up, measurements used including any biochemical verification
6. Analysis method

The two reviewers also assessed the risk of bias by including their judgement in the data extraction table of the following:

1. Was the sequence generation adequate?
2. Was allocation concealed?
3. Who was blinded?
4. Were incomplete data addressed? (e.g. Was there an intention-to-treat analysis? What was the attrition rate? Was there differential attrition by group assignment or by baseline smoking status?)
5. Was the study free of selective reporting? (e.g. Were all of the study’s pre-specified outcomes reported?)
6. Was the study free of detection bias? (e.g. Was there biochemical verification of self-report smoking status? In cases of self-report, did participants believe their answer would affect their receipt of incentives?)

The two reviewers compared their data extraction forms and discrepancies were resolved by consensus.

**Stage 3: Analysis**

Where possible, we contacted the trial authors to request missing data. We excluded participants for whom no outcome data were available, rather than conducting an intention-to-treat analysis of all randomized participants with imputed values for the missing data. In smoking cessation trials it is generally accepted that missing data should be imputed as ‘failures’ (i.e. smoking), as this is a conservative approach and is a plausible outcome in such trials. In most other instances an imputation approach is generally not recommended because studies with imputed data may be given more weight than they deserve if entered as dichotomous data and none of the assumptions made when imputing data are likely to reflect the truth (Higgins 2011). Proceeding with an available case analysis is a more conservative approach than imputing that those lost to follow-up have not started smoking. This approach produces a less conservative result compared with imputing that those lost to follow-up all started smoking, but we do not think this is particularly plausible in this context.

We calculated a risk ratio (RR) for the outcome for each trial, defined as (number of smokers in the intervention group who were nonsmokers at baseline/ total number of baseline nonsmokers randomized to the intervention group) / (number of smokers in the control group who were baseline nonsmokers/ total number of baseline nonsmokers randomized to the control group). Adjusted RRs from cluster-randomized trials using schools as the unit of analysis were obtained by adjusting the original (non-adjusted) RRs using an intra-class correlation coefficient (ICC) of 0.097 (ICC for current smoking status averaged among all ethnicities) as reported by Siddiqui et al (Siddiqui 1996). An RR less than 1 favoured the intervention, indicating that more participants abstained from smoking in the intervention group compared to the control group.

We used the Chi² test and the I² statistic to assess heterogeneity among studies and found no evidence of significant heterogeneity reflecting the fact that included trials were sufficiently homogeneous in terms of participants, interventions and outcomes assessed. We therefore combined eligible studies to calculate an estimated pooled weighted average of RRs using the Mantel-Haenszel fixed-effect method, with a 95% confidence interval. We performed separate meta-analyses for randomized and non-randomized controlled trials.

**Assessment of reporting biases**

We had planned on preparing a funnel plot to investigate for the possibility of reporting biases (if there were at least 10 included studies). There were too few studies for this.

**Subgroup analyses**

In the event of significant heterogeneity, we had planned for possible subgroup analyses including: type of intervention (solely financial rewards versus financial rewards plus other smoking cessation intervention; staged versus one-off incentive); type of incentive (individual versus rewards to third parties; lottery versus definite payment of a specified reward amount); and size of the incentive (low, high). Owing to the fact that we found no significant heterogeneity among studies and because there were insufficient data, we did not carry out these analyses.

**Sensitivity analysis**
While we performed the meta-analysis separately for randomized and non-randomized controlled trials, there were too few studies to undertake a sensitivity analysis by first including, then excluding less rigorous trials (as originally planned).

RESULTS

Description of studies
See: Characteristics of included studies; Characteristics of excluded studies; Characteristics of ongoing studies.

We identified 581 potentially relevant records in our search conducted in May 2012 (Figure 1). The title and abstracts were reviewed by one author (VJ) and records that clearly did not relate to the research question were excluded. Fifty full text records were independently co-reviewed by two authors (VJ and DT) and evaluated against the pre-specified inclusion criteria. We identified seven controlled studies (from 19 records) that met our inclusion criteria. We found two study protocols for relevant studies that have not yet been published (listed in the Characteristics of ongoing studies table). The 28 excluded studies are listed in the Characteristics of excluded studies table with reasons for their exclusion.

Figure 1. PRISMA study flow diagram of search results
Included studies
All of the seven included studies rewarded smoking abstinence with a minimum follow-up period of six months after the start of the intervention. Full details of the included studies are given in the Characteristics of included studies table. Where there were multiple reports of the same study, these appear in the reference list of ‘included studies’, the main report is indicated by an asterisk. All included studies took place in a school setting. Three studies were undertaken in Germany (Isensee 2012a; Schulze 2006; Wiborg 2002), and one each were undertaken in the Netherlands (Crone 2003), Finland (Vartiainen 1996), Canada (Kairouz 2009) and the United States (Burke 1992). All studies were cluster-controlled trials, with allocation by school. Three studies were randomized controlled trials (Crone 2003; Isensee 2012a; Schulze 2006). The remainder were controlled trials without randomization.

Target group of intervention
All of the studies targeted school students. Kairouz 2009 enrolled primary school students (sixth grade classes, typically aged 11 to 12). The remainder of the studies targeted high school students (seventh and eighth grades, typically 12 to 14 years old).

Types of incentives
All but one (Burke 1992) of the included studies was a trial of the so-called ‘Smokefree Class Competition’ (SFC) or a closely related variant. The SFC originated in Finland in 1989 and since then has grown into one of the largest smoking prevention programmes in Europe (Hanewinkel 2010), with funding from the European Commission. The general requirements for the competition are as follows: (i) at least 90% of the class must agree to participate (i.e. participation is voluntary); (ii) classes sign a contract and commit to remain smoke free for six months (usually defined as greater than or equal to 90% of the class is non-smoking); (iii) classes and teachers monitor the smoking status of students and report regularly to the competition organisers as to whether at least 90% of the class remains non-smoking (usually monthly) (IFT-NORD 2009). If classes report less than 90% of the class are smoke free, they are dropped from the competition. At the end of the six months, the classes in the competition that have remained smoke free have the chance of winning a prize, usually via a prize draw or lottery.

There is some flexibility in the implementation of the SFC competition to allow different countries to adapt the programme to suit their context. This is evident in the studies included in this review. In addition to the main competition prize, classes may be awarded other incentives for participating (Kairouz 2009). The final prize draw may also be contingent on additional factors. For example, in Crone 2003, competition prizes were available to six classes with less than 10% smoking and a “photo best expressing a non-smoking class” (p.676), decided by a jury panel. In other studies, it is clear that smoke free classes went into a lottery to win a prize (Schulze 2006; Vartiainen 1996). In Kairouz 2009 and Wiborg 2002, it is less clear exactly how the prizes were awarded to smoke free classes. Definitions of ‘smoke free’ also differed. Vartiainen 1996 defined smoke free classes as classes who reported 100% non smoking; the other studies in this review set a tolerance level of 90% or more smoke free.

The prizes in the included SFC competition trials ranged from special activities (e.g. hip-hop classes, Kairouz 2009) to monetary prizes (Crone 2003; Vartiainen 1996) and class trips (Isensee 2012a; Schulze 2006; Vartiainen 1996; Wiborg 2002). Several studies did not provide detailed accounts of the type and amount of incentives. Kairouz 2009 reported that teachers and students received participation incentives but did not detail what these were. They also reported that “participating classes were eligible for a half-day surprise activity (e.g. a hip-hop dance with a DJ)” (p.475) but did not report whether this was specifically the competition prize or how eligible classes were selected to receive these activities, and we were unable to obtain further details from the authors. We have assumed in the absence of further information that the half-day surprise activities were rewarded to smoke free classes. Isensee 2012a, Schulze 2006 and Wiborg 2002 all reported that the grand prize was a class trip. They reported awarding other prizes to smoke free classes, did not elaborate on these.

Monetary prizes were distributed in the trials conducted by Crone 2003 and Vartiainen 1996. In Crone 2003, prizes of EURO220 to EURO450 were given to six classes with less than 10% smoking and “a photo best expressing a non-smoking class” (p.676). In Vartiainen 1996, smoke free classes entered a lottery to win four main prizes of US$2000 and 10 second prizes of US$200; the grand prize was a class trip. In this study, prize money could be used in any way the winning classes chose.

The one study that was not a trial of the SFC (Burke 1992) was a controlled trial in which schools in two communities were assigned to the intervention, with schools in a third community acting as controls. In the first competition, intervention communities competed against each other and students in the community with lower smoking rates at the end of the project were rewarded with a movie pass and a voucher for free ice-cream. In a second competition, students in the intervention classes with most improved knowledge about smoking were rewarded with a T-shirt with the project logo on it.

Incentives as part of a larger programme or stand alone
Five studies reported combining the competition with some education about the health effects of smoking (Burke 1992; Crone 2003; Kairouz 2009; Schulze 2006; Vartiainen 1996). In Burke 1992, both intervention and control classes received an education programme (six sessions) about the health and social effects of smoking which included skills training for resisting peer and media pressures to smoke.
In the trials of SFC competitions, Vartiainen 1996 reported that contact teachers in the classes organised health education sessions about smoking but it was not clear whether these sessions were delivered to both intervention and control groups. Crone 2003 reported that intervention classes received three lessons on knowledge, attitudes and social influence before classes signed the contract not to smoke for five months. Additionally, two video lessons on smoking and social influence were available as an optional extra during the intervention period. In Schulze 2006, the intervention included weekly curricula consisting of health information about smoking and strategies for how to quit smoking and resist peer pressure to smoke. Kairouz 2009 reported that the intervention arm received a six month programme consisting of didactic material, a teacher’s guide and resources to improve knowledge about health and social effects of smoking. The dose and frequency of this programme was not clear.

Theoretical basis of intervention

The best practice guide for the SFC competition (IFT-NORD 2009) reports that the SFC relies on four theoretical models for behavior modification. The first is learning theory which asserts that positive reinforcement increases the probability of producing a given desirable behavior, such as not smoking. The SFC also incorporates a ‘social contract’ to remain smoke free. The second is social learning theory which states that people learn from one another, via observation, imitation, and modelling. In the SFC, students serve as models for non-smoking behavior for their peers. Thirdly, the theory of planned behavior states that personal attitude, subjective norms, and perceived behavioral control together shape an individual’s behaviors. Finally, SFC relies on developmental psychology, in that the developmental orientation of adolescents is towards short term goals, and hence the competition’s emphasis is on positive short term consequences of non-smoking behaviour. The studies that trialled the SFC variously reported an underpinning theoretical framework.

Crone 2003 based their intervention on a ‘social influence’ model, relying on peer pressure directed at young people to both resist smoking and to promote not starting to smoke. Kairouz 2009 reported that the premise for their intervention rested on positive reinforcement for not smoking to stimulate a desired behavior, but did not reference a specific social theory. Isensee 2012a reported that the intervention was based on principles of correcting social norms (i.e. correcting the common overestimation of smoking by adolescents) and fostering commitment to a social contract. Wiborg 2002 cited learning theory as the theory underpinning the SFC competition trialled in Germany, reported on in this paper. Schulze 2006 and Vartiainen 1996 did not report an underlying theoretical framework for the intervention, but both were trials of the SFC.

Burke 1992 referenced Fishien and Ajzen’s (Ajzen 1977) theory of reasoned action as the theoretical framework for their intervention. This theory posits that preventing the initiation of a voluntary behavior, such as smoking, is dependent on changing smoking-relevant beliefs or subjective norms, or both. Burke 1992 used group competitions with rewards as persuasive interventions designed to change beliefs and norms.

Risk of bias in included studies

Summary assessments of the risk of bias for key areas in each of the included studies are shown in Figure 2 and Figure 3. Full details of risk of bias assessments for each study can be found in the Characteristics of included studies table.

Randomization, sequence generation and allocation concealment

Three studies were randomized controlled cluster trials (Crone 2003; Isensee 2012a; Schulze 2006). Isensee 2012a and Schulze 2006 stratified schools according to school type ('Gymnasium' and 'Sekundarschule' schools; gymnasium schools enrol high academic achieving students). In the remaining four studies randomization was not used (Burke 1992; Kairouz 2009; Vartiainen 1996; Wiborg 2002).

In two of the four quasi-experimental studies, the control group was matched to the intervention group (Kairouz 2009; Wiborg 2002). In Kairouz 2009, two control schools were matched to each intervention school according to location and a social deprivation index. In Wiborg 2002, the same proportion of classes from different grades and school types as in the intervention group was randomly selected from classes in a city in Germany that had not been invited to participate in the competition. Burke 1992 and Vartiainen 1996 did not match intervention and control groups. Two of the three RCTs (Crone 2003; Isensee 2012a) reported adequate randomization procedures (sequence generation and allocation concealment). The other RCT (Schulze 2006) did not report their process for sequence generation or allocation concealment. Several studies reported significant differences between intervention and control groups at baseline, which is not uncommon in cluster randomized trials where groups and not individuals are the unit of randomization. Burke 1992 and Kairouz 2009 did not provide data on demographics (age, sex, socioeconomic status (SES)) or smoking status for both intervention and control groups at baseline. Kairouz 2009 did report a comparison of baseline characteristics for those who completed follow-up, with significant differences by age, school location and social deprivation index (adjusted for in their analyses). Vartiainen 1996 only provided a baseline comparison on smoking status. A higher proportion of the control group reported daily smoking at baseline compared with the intervention group, which was adjusted for in the final reported analysis. Wiborg 2002 did not report baseline group differences in SES or ethnicity. Smoking prevalence at baseline was higher in the control group than in the experimental group, although the difference was not statistically significant. There were no baseline differences in age or sex.

Blinding (performance bias and detection bias)

None of the included studies adequately described whether participants or personnel were blinded during the study but given the nature of this type of intervention, it is unlikely. It was considered that despite this, the outcome is unlikely to have been significantly influenced by lack of blinding.

In most of the studies that evaluated the SFC (Crone 2003; Isensee 2012a; Schulze 2006; Vartiainen 1996; Wiborg 2002) we judged the risk of detection bias as low, as efforts were made by study investigators to dissociate the collection of results from the SFC itself, and we therefore judged differential misreport between the two groups to be unlikely. None of the included studies reported whether the research investigators were blinded when it came to analysing study outcomes. Kairouz 2009 reported that there were significantly more students in the intervention group who reported ever-smoking at baseline but subsequently denied ever smoking at follow-up, compared with control (24% vs 16%). We therefore judged this study to be at high risk of detection bias. None of the studies trialling the SFC used biochemical verification of self-reported smoking status. Some authors argued that interpretation of cotinine results in a population who are likely to be smoking sporadically, rather than daily, would not be meaningful (Crone 2003; Kairouz 2009).

Burke 1992, the only study that was not a trial of the SFC competition, did not report whether the research investigators were blinded to participants’ intervention group when analysing the data. Saliva samples were collected when the surveys were administered to measure salivary thiocyanate (TCN). The TCN results were used to justify the use of self-report, except at baseline, when 39 self-reported ‘never smokers’ were reclassified as ‘occasional smokers.’

Incomplete outcome data

With the exception of Burke 1992, all studies struggled with significant attrition at longest follow-up. Burke 1992 and Isensee 2012a were the only studies assigned a low risk for attrition bias: Burke 1992 had only small numbers lost to follow-up, and Isensee 2012a conducted attrition analyses and found interaction effects only for age and school type.

Three studies in which differential attrition by smoking status or group assignment was found, or in which over half of the participants were lost to follow-up, were rated at high risk of attrition bias (Crone 2003; Schulze 2006; Wiborg 2002). The remaining studies were rated at unclear risk as, though over 50% of participants were followed up, it was unclear if differential attrition was present.

Differential attrition between the two groups of baseline non-smokers could put the results at risk of bias. For example, if more baseline non-smokers were lost to follow-up at in the control group, this might bias the results towards over-estimating the effect of the intervention in preventing smoking.

Selective reporting

For all included studies there was insufficient information for us to make an assessment of risk regarding reporting bias. None of the
records clearly identified pre-specified primary outcomes. Only one study referred to a published study protocol (Isee 2012a). While the study publication reported on smoking status (the only primary outcome relating to behavior), it did not report on other study outcomes, such as knowledge, attitudes and intention to use tobacco (Hanewinkel 2007b).

**Effects of interventions**

**Outcomes**

Only one study (Burke 1992) included a biochemical assessment of smoking status. The remainder relied on self-report. Definitions of smoking at follow-up differed between the studies. Crone 2003 defined smoking at follow-up as current smoking (including daily, weekly and experimental smokers). The definition of current smoking used by Schulze 2006 also included irregular (less than weekly) smoking. Wiborg 2002 measured four week prevalence of smoking and Vartiainen 1996 measured daily smoking as the outcome variable. In Kairouz 2009 and Isee 2012a, the outcome was defined as ‘ever smoking’ (even just a puff). Only one study used a different definition of smoking at baseline than at follow-up. Schulze 2006 defined ‘current smokers’ at baseline as regular smokers whereas at follow-up ‘current smokers’ included both regular and irregular (at least one a week) smokers. Where possible we have used the most conservative definition (i.e. ever smoking) in assessing the effects of the intervention. This measure is thought to be most representative of smoking initiation among baseline non-smokers. Raw outcome data, especially in the earlier studies, were often difficult to extract and we needed to contact the authors of six of the seven included studies for more data. Three of the six authors provided additional data for this review (Crone 2003; Isee 2012a; Wiborg 2002). All studies reported a follow-up period from the start of the intervention of more than six months. The shortest long term follow-up was reported by Kairouz 2009 (between 10 and 18 months) and the longest was 24 months (Schulze 2006).

**Results**

**Primary outcome**

Of the seven trials identified, only five had analysable data relevant for this review and contributed to the meta-analysis (6362 participants in total who were non-smokers at baseline; 3466 in intervention and 2896 in control). Due to different reporting methods used, and participants included, we were unable to quantify the total number of participants in included studies. The pooled risk ratio (RR) for the more robust randomized controlled trials (RCTs) suggests that, from the available data, there is no statistically significant effect of incentives to prevent smoking initiation among children and adolescents in the long term (RR 1.00, CI 0.84 to 1.19, Analysis 1.1). The pooled result from two controlled clinical trials (CCTs) also did not detect a significant effect (RR 0.81, 95% CI 0.61 to 1.08). Details of the results of the seven included studies in this review are tabulated in Analysis 2.1 and Analysis 2.2. In these tables, we have reported smoking status at the longest follow-up, including both the summary statistics provided in the original trial reports (if available) and our adjusted RRs. Burke 1992 and Vartiainen 1996 did not provide data at follow-up regarding the outcome of interest for this review (smoking status of participants who reported no smoking at baseline). Burke 1992 analysed mean salivary thiocyanate (TCN) levels between groups at 18 months follow-up and found a non significant higher mean TCN level among baseline never smokers in intervention (560 mcg/mL, standard deviation (SD) 403) versus control participants (514 mcg/mL, SD 424). Vartiainen 1996 reported on the increase in daily smoking prevalence at follow-up. There was a short term effect of the intervention, with a lower daily smoking prevalence in the intervention (11.1%) versus the control group (16.4%) at one month after the competition, but this was not sustained long term. From baseline to longest follow-up (18 months), daily smoking increased by 10.8% in the intervention group and 11.2% in the control group.

Of the remaining five studies (all trials of the SFC competition), three (Crone 2003; Isee 2012a; Kairouz 2009) appropriately accounted for the clustered design in the analyses of their data. For consistency, we reanalyzed the data from all five studies to account for clustering and to enable us to conduct a meta-analysis as planned using the Mantel-Haenszel fixed-effect method. In order to run these analyses, we needed to know the number of clusters (schools) at follow-up for each study. We were able to extract this data from the paper or directly from authors for all of the studies, expect for one (Wiborg 2002). In the case of Wiborg 2002, we knew the number of classes in both groups at follow-up and used this data to estimated a plausible number of schools. The authors reported that five classes did not participate in the study due to organizational and structural changes in their schools, indicating that these classes were from more than one school. Assuming that these classes were from at least two schools, we estimated a number of classes per school ratio (5/2 = 2.5). We then estimated the number of schools in the intervention and control groups, based on this ratio. The classes/school ratio (2.5) estimated for Wiborg is similar to that of two other studies (Isee 2012a and Schulze 2006) for which we had data but less than in Crone 2003 (7.5). While we did not adjust for any baseline differences between the groups in these five trials, our results are similar to authors' adjusted analyses where these have been reported. Only one study, a non-randomized controlled trial (Wiborg 2002), reported a significant effect of the intervention on the prevention of smoking at the longest follow-up. At the posttest (six months after the start of the intervention and one month after the inter-
vention ceased), Wiborg 2002 reported a significant differences in four week smoking prevalence in the intervention versus the comparison group. Of the intervention students, 7.8% reported having smoked during the past 4 weeks compared to 13.9% of the control students. A significant difference persisted 12 months after the start of the intervention. At this time, four week smoking prevalence of baseline non-smokers was reported as 17% in the intervention group versus 21.3% in the comparison group. The results reported in the paper were statistically significant (odds ratio (OR) 1.36, CI 1.04 to 1.76). For consistency, we have applied the inverse of the odds ratio reported by Wiborg, so that an OR less than 1 favours the intervention, indicating that more participants abstained from smoking in the intervention group compared to the control group; the inverse OR at 12 months is 0.74, 95% CI 0.96 to 0.57. However, our reanalysis to adjust for clustering found that the risk of initiating smoking at follow-up was non-significantly less in the intervention, compared with the control group (adjusted RR 0.81, 95% CI 0.53 to 1.23).

The other non-randomized control trial for which we had appropriate outcome data (Kairouz 2009) reported that 14% of the intervention group initiated smoking during follow-up, compared with 16% in the control group. Our reanalysis produced a similar result to that of Wiborg 2002 (RR 0.81, 95% CI 0.55 to 1.20).

None of the three RCTs (Crone 2003; Isensee 2012a; Schulze 2006) demonstrated a significant long term effect of the intervention on smoking initiation, although Crone 2003 reported a significant impact at the short term follow-up. At the first posttest in Crone 2003 (eight months after the start of the intervention and two months after the intervention ceased), 9.6% of baseline non-smokers reported current smoking in the intervention group, compared with 14.2% in the control group. The effect of the intervention on initiation at 19 months was not reported in the paper, owing to the large number of non-responders at the second follow-up point. Our reanalysis with outcome data provided from the authors found that the risk of initiating smoking at follow-up was non-significantly less in the intervention, compared with the control group (adjusted RR 0.92, 95% CI 0.53 to 1.61).

Schulze 2006 reported that a similar proportion of the intervention (62.1%) and control groups (61.5%) remained never-smokers at longest follow-up. When we reanalyzed the data for current smoking prevalence among baseline non-smokers at follow-up we found a result similar to that reported in the paper (RR 0.98, 95% CI 0.77 to 1.24).

Isensee 2012a reported that there was no intervention effect on smoking initiation among baseline ‘never smokers’ during the study period, but did report an effect among baseline experimental smokers. The probability among baseline experimental smokers to progress to established use was higher for those who did not participate in the intervention; that is, students in the control group combined with students from classes who were randomized to the intervention group but opted not to participate in the trial (adjusted hazard ratio as reported in the paper =1.45, CI 1.00 to 2.10). In our reanalysis to assess the impact of the competition on smoking initiation, we compared data for the group that were randomized and participated in the intervention versus the control group. The classes that were randomized to the intervention group but opted not to participate in the trial were excluded (instead of being combined with the control group). We thought this was a more conservative comparison than including them as control participants because classes who were randomized to the intervention but did not participate had a higher smoking prevalence at baseline. We found that the risk of initiating smoking was 5% more likely in the intervention group, compared with the control group; however the confidence intervals were wide and encompassed possible positive and negative effect (RR 1.05, 95% CI 0.80 to 1.38). It is notable that Isensee 2012a was the most robust study in this review, judged to be at the lowest risk of bias. We conducted a meta-analysis separately by study design (RCTs vs non-RCTs), combining the findings from the independent studies to produce a pooled estimate of the effect of the intervention on smoking initiation. All the included studies in the meta-analysis were of SFC competitions. The pooled point estimate for the non-randomized RCTs (2 studies, n = 3306 participants), which were significantly limited by multiple biases that favoured the intervention, was not a statistically significant result (RR 0.81, 95% CI 0.61 to 1.08). The result for RCTs (3 studies, n = 3056 participants) suggests that SFC competitions did not statistically significantly prevent smoking initiation (RR 1.00, 95% CI 0.84 to 1.19). The confidence intervals indicated that participants in the SFC competitions may be anywhere between 16% less likely and 19% more likely to initiate smoking, compared with those who do not take part in a SFC competition.

Secondary outcomes

We were not able to assess whether the amount or type of incentive affected prevention of smoking. This is because data on incentives were incomplete and because the small number of studies makes these comparisons difficult. We were also unable to assess whether incentives were more or less effective in combination with other interventions to prevent starting smoking owing to the fact that of those studies that clearly provided an additional educational component to their incentive programmes (Crone 2003; Kairouz 2009; Schulze 2006), none measured the “incentive effect” of the intervention (i.e. they did not include an arm that received additional education but no incentive). The effect sizes were small across all studies with analysable data and did not suggest that programmes that combined incentives and education (Crone 2003, Kairouz 2009, Schulze 2006) were more effective than those using incentives alone (Isensee 2012a and Wiborg 2002).

Only one study rigorously assessed costs associated with the incentive programmes. Hoeflymayr 2008 analysed the cost-effectiveness of the SFC competition reported on by Wiborg 2002, using economic modelling based on estimates of reduced smok-
ing prevalence in the intervention group and models of assumed future smoking behaviour and cessation. This report did not examine the cost-effectiveness of preventing initiation. One study specifically examined whether participants in the intervention group might have made false claims about their smoking status. Kairouz 2009 reported that their social contract prevention programme may have encouraged student smokers to misrepresent their smoking status at follow-up in order to increase their class chances of winning a prize. This study found large numbers of ever-smokers at baseline subsequently denying ever smoking at follow-up. In total, 16% of baseline ever smokers in the control group denied smoking at follow-up, compared to 24% in the intervention group. In both groups, denial was more frequent among participants who had smoked the lowest number of cigarettes at baseline, perhaps suggesting an element of recall bias. Isensee 2012a also considered under-reporting of smoking status among intervention participants and reported that inconsistent response patterns over time did not differ by intervention status (data not presented).

Finally, one study assessed whether the SFC competition trialled by Isensee 2012a increased bullying or perception of isolation among students (Hanewinkel 2002). When compared with control classrooms on three dependent variables - being victimised, active bullying or being isolated - adjusted ORs indicated no significant differences at post-test for the intervention groups. Kairouz 2009 reported that after exposure to SFC competition, intervention participants were more likely than control participants to report that people “should not hang out with smokers” (14% versus 11%) and that they, themselves would “not want to be friends with a classmate who smokes” (28% versus 25%). However, it should be noted that the prevalence of these attitudes fell in both groups at the follow-up measurement and that the authors did not report on the proportion of participants in both groups who perceived themselves as marginalized at baseline and follow-up (arguably a more sensitive indicator of whether the competition resulted in the perception of isolation among students). Theoretically, a negative outcome of young people being told not to smoke for an incentive may be that youth smoke in reaction against directives from authority figures (i.e. the concept of “forbidden fruit,” Sussman 2010) but we found no evidence of this in the studies included in this review.

No other studies reported on secondary outcomes for this review (dose response of the amount of incentive, costs and any adverse effects).

**DISCUSSION**

Most of the studies in this review were trials of the so-called Smoke Free Class (SFC) competition. At the core of this competition is the commitment of classes not to smoke for a six month period (the social contract) and rewarding smoke free classes with prizes in a competition. While this competition has been widely implemented in schools in more than 20 European countries (Isensee 2012a), there has been considerable controversy about its effectiveness to prevent smoking among young school students in the long term. A lively debate has taken place in academic journals between those who argue for the effectiveness of this competition and those who argue that their effectiveness has been over-stated (Etter 2006; Hanewinkel 2007; Hanewinkel 2006; Potschke-Langer 2006). While one study of the SFC competition in this review reported a long term significant effect of incentives, the study was judged to be at high risk of selection bias and results were not adjusted to take into account the cluster design of the study. When we reanalyzed the data, the effect was non-significant. The pooled risk ratio (RR) for the more robust RCTs (3 studies, n = 3056 participants) suggests that, from the available data, there is no statistically significant effect of incentives to prevent smoking initiation among children and adolescents in the long term (RR 1.00, 95% CI 0.84 to 1.19). Pooled adjusted results from the two less robust trials also did not detect a significant effect (RR 0.81, 95% CI 0.61 to 1.08).

All of the studies in this review were cluster trials which, compared with individually randomized trials are more complex to design, require a larger number of participants to obtain equivalent statistical power, and require more complex analysis (Campbell 2004). They are also prone to several risks of bias (Giraudeau 2009), as can be seen in the trials included in this review. For example, of the three cluster RCTs in this review, one (Schulze 2006) may have been susceptible to selection bias as recruitment occurred after randomization and three classes assigned to control refused to forego the intervention and were subsequently included in the intervention group. In the four non-randomized cluster trials there were baseline imbalances between groups. In two of these (Vartiainen 1996; Wiborg 2002), the intervention group was comprised of schools that had already registered to participate in the competition, so there may have been intrinsic differences in the level of motivation between intervention and control groups. Attrition was a significant issue for these studies. Only one study managed to retain 80% of the sample at the longest follow-up (Burke 1992) and only one study appropriately reported on number of clusters (schools) and number of participants at each time point (Crone 2003). Some studies failed to adequately report reasons for attrition or to adequately assess effects of attrition on the distribution of confounding variables across groups at final follow-up (Crone 2003; Kairouz 2009; Schulze 2006; Vartiainen 1996). None of the studies reported an intention-to-treat analysis for smoking initiation. While this may not be appropriate for studies assessing smoking initiation, it does mean that in these studies there was a significant amount of missing data in the final analyses. In addition to risk of biases, there were other limitations to the conduct of the trials. Only two studies reported a sample size calculation. These were appropriately adjusted to account for clustering effects but because of loss to follow-up, both studies were underpowered to
demonstrate a significant effect. Finally, only three studies appropriately adjusted their analyses to account for clustering. Overall, these studies were of variable quality and we would recommend that future cluster RCTs of incentives adhere to the extension to the CONSORT statement for cluster randomized trials to improve the quality of the evidence in this area (Campbell 2004).

The other limitation of the studies in this review is the variability in the reported detail of the interventions, both in terms of the dose and any additional components delivered, such as education. Where detail was provided, the incentives described were small (e.g. hip hop classes, a movie pass or a voucher for ice-cream) to moderate in size (the most recent study distributed six prizes between EURO220 and EURO450 to classes). In the SFC competitions, smoke free classes were not guaranteed an incentive, but instead went into the draw for prizes or had to satisfy additional criteria to win a prize (e.g. in the study by Crone 2003, classes were awarded a prize if they were smoke free and produced a photo judged as best expressing a non-smoking class). Only one study (Crone 2003) reported on how many prizes were awarded. Additionally, all the included studies distributed the incentive to whole classes, rather than giving it directly to individuals who reported or were confirmed to have remained abstinent from smoking. This is in contrast to studies that have tested the efficacy of competitions and incentives on smoking cessation, which generally have rewarded individual quitters (Cahill 2011).

This begs the question about whether small to moderately sized incentives that successful participants are not necessarily guaranteed to receive are sufficient motivation for children and adolescents to abstain from smoking. In the Cochrane review of the effectiveness of competitions and incentives for smoking cessation, only one included study offered evidence that incentives may improve long term smoking cessation. The authors of this trial suggested that they had an adequate sample size to detect an effect, in addition to a substantial reward to sustain the target behaviour (abstinence) (Volpp 2008). In this study a total of US$750 was given to individuals incrementally for completion of a smoking cessation programme and sustained abstinence at 9 or 12 months. It may not be financially, logistically or ethically feasible to distribute incentives to individuals who do not take up smoking. Certainly, the issue of confirming non-smoking status needs consideration, as most biological indicators of smoking in use only measure recent tobacco use (Dolcini 2003). It may also not be financially feasible to distribute incentives to all classes who remain smoke free, especially when considering scaling up the competition to a regional or national level. Nevertheless, future trials should consider the size of the incentive and describe this in detail, as well as the number of prizes distributed relative to the number of smoke free classes. An important question that remains unanswered is whether the efficacy of incentives for smoking prevention might be different depending on whether the reward for behaviour change was certain or only probable (i.e. determined by a prize lottery); behavioral psychology suggests that outcomes may differ under these conditions (Tversky 1981). The final limitation of the included studies is that in the three studies that provided an additional educational component to their intervention, they did not assess the “incentive effect” of the intervention, over and above the additional education.

Recently, another meta-analysis has been published assessing the effects of the SFC competition on current smoking among adolescents (Isensee 2012b). Isensee 2012b reported rates of current smoking at baseline and longest follow-up between intervention and control groups in five of the SFC studies included in this review (Crone 2003; Isensee 2012a; Schulze 2006; Vartiainen 1996; Wiborg 2002) and pooled the RRs of smoking at follow-up. This yielded a RR of 0.86 (95% CI 0.79 to 0.94). The authors concluded that there is “some evidence that SFC contributes to smoking prevention in adolescents” (Isensee 2012b, p.114) We would argue that this review suggests some evidence for a reduction in smoking among intervention participants but that measuring the effect of the competition on smoking prevention required an assessment of the smoking status of baseline non-smokers at follow-up. Further, as the authors noted, there were several limitations to their review; they combined RCTs and non-RCTs in their meta-analysis, did not assess the risk of biases in the studies, and did not make any adjustment to the data for the cluster design of these trials where this had not been undertaken in the original studies. Potschke-Langer 2006 argue that if smoking prevention (or delay of smoking onset) is the primary aim of the SFC competition, studies should be comparing proportions of never smokers at follow-up, as a comparison of smoking prevalence only tells us about the respective groups at one point in time and not about smoking dynamics over time (i.e. a young person may change their smoking status during the intervention period). This is an issue raised by Isensee 2012a in the most recent and the most robust study of the SFC competition. In this study, there were reportedly no group differences in the frequency of initiation of smoking among baseline never smokers. However, the probability among baseline experimental smokers to progress to established use over the study period of 19 months was higher for non-participants of the competition. The authors conclude that the “salient effect of the intervention is that it reduces the risk of a progression into higher stages of use among experimental smokers” and suggest that perhaps early experimental smokers are the group most amenable to intervention effects (p.339). This is a question that is worthy of further investigation and future trials should assess intervention impact on both smoking initiation and progression.

Although the interventions covered in this review run the risk of deception by smokers regarding their smoking status in order to increase their chances of winning a prize, there is not a lot of evidence to support this. While one study reported that inconsistent response patterns were higher in the intervention than in the control group, this may have been affected by recall bias (Kairouz

Incentives for preventing smoking in children and adolescents (Review)

Copyright © 2012 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.
Several studies went to some lengths to disguise the fact that the outcome assessments were not linked to the competition to reduce misreporting of smoking status (reporting on smoking status for the competition was a separate process). By purposefully de-linking the evaluation of the SFC to the competition itself (reporting of smoking status of participating classes for the competition was separate from the survey that measured smoking outcomes for evaluative purposes), students may have been less likely to under-report their smoking status, although this cannot be completely ruled out. Only one study (Hanewinkel 2010) has been conducted to investigate other possible unintended consequence of these competitions; namely, bullying or perceptions of isolation among students who cause their class to drop out of the competition because they smoke. This study found that there was no significant effect of the competition on bullying or perceptions of isolation. Kairouz 2009 found that intervention participants were more likely to report that people “should not hang out with smokers” and that they themselves “would not want to be friends with a classmate who smokes,” but the prevalence of attitudes in both groups fell at follow-up and the authors did not report on the proportion of participants in both groups who perceived themselves as marginalized.

One final point relates to the transferability of this evidence to other contexts. All studies included in this review were conducted in high income countries. There was variability across studies in the reporting of the proportion of participants who were from minority ethnic or lower socioeconomic backgrounds. Where this was reported and able to be interpreted, the studies included a smaller proportion of participants representative of minority groups (Burke 1992; Crone 2003; Isensee 2012a) and low socioeconomic backgrounds (Crone 2003). Mercken 2012 reanalysed data from the study reported by Crone 2003; a multilevel model was tested separately for adolescents in each of the categories of the two included SES indicators in this study (educational level and employment status of parents). These stratified analyses found that the overall significant short term effect of the intervention was only present for high SES adolescents (Mercken 2012). Further, when these additional analyses were stratified by gender, the intervention appeared to only be effective among boys with higher parental educational levels (OR 0.24, 95% CI 0.07 to 0.79), although these results should be interpreted cautiously as sample size calculations were not based on these subgroup analyses. Future studies should report details about the sociodemographic characteristics of participants at baseline and follow-up, and if possible analyse their results by ethnic and socioeconomic group to be able to assess whether incentives differentially affect participants from these backgrounds.

Limitations of this review include that we focused our analysis solely on the effectiveness of incentives to prevent smoking initiation (as per our protocol) and did not examine the impact of incentives on progression of smoking. Findings from the most recent study of the SFC competition suggest that the effect of the competition might be greater for occasional smokers, compared with non-smokers at baseline. Another limitation that may have biased our results is that our outcome data were incomplete. We could not extract appropriate data for this review from two studies (Burke 1992; Vartiainen 1996) or directly from the authors, and we had to estimate the number of clusters for another study (Wiborg 2002). We concentrated on getting outcome data from authors, rather than further detailed process information (e.g. programme implementation), which is also a limitation of this review.

**Authors’ Conclusions**

**Implications for practice**
- Currently, there is no high quality evidence that incentives aimed at children and adolescents prevent smoking initiation in the long term.
- Specifically, there is no statistically significant long term effect on smoking initiation of the SFC competition. Any short term reported success dissipated over time. An important finding in this review is that after adjustment for clustering correlation the one longer-term significant finding of treatment effect (Wiborg 2002) was no longer significant. These findings raise some doubts about further expansion of the competition if the specific aim of the programme remains to prevent smoking uptake. There is some preliminary evidence that the SFC competition may reduce the risk of a progression of smoking among experimental smokers.
- Incentives may theoretically increase the risk of false claims by participants, as well as introduce the potential of bullying and isolation of smoking students when incentives are distributed to a group (rather than individuals). Currently, there is little robust evidence to suggest that these are significant unintended consequences of such interventions, but this has not been the subject of much research.

**Implications for research**
- Future studies might investigate the effectiveness of incentives given to individual participants to prevent smoking uptake.
- Future trials of the SFC competition or any incentive programme where the incentive is given to a group (e.g. a school class) versus individuals should carefully consider the size of the incentive and the number of incentive prizes relative to the number of successful smoke free classes at the completion of the competition, and should also attempt to measure and report the
effectiveness of the incentives programme over and above other additional intervention components (e.g. anti-tobacco education).

- The respective merits of cash payments versus non-financial incentives should be assessed and compared.

- Future research should consider elements of behavioral psychology to explore whether the efficacy of incentives might be different depending on whether the reward for not smoking is certain or only probable (i.e. determined by a prize lottery).

- Trials should describe the intervention components in detail and adhere to the extension to the CONSORT statement for cluster randomized trials to improve the quality of the evidence in this area.

**ACKNOWLEDGEMENTS**

We would like to thank Reiner Hanewinkel, Barbara Isensee and Mathilde Crone for supplying additional data or clarification. We would especially like to thank Reiner Hanewinkel for his assistance in assessing the eligibility of the German records that were returned in our systematic search of the literature. We also thank Patyvan Anderson for his assistance in assessing the eligibility of one Swedish record. We gratefully acknowledge the assistance of Hilde Stromme, Clinical Librarian at Northern Territory Department of Health for her assistance with our search strategies and Lindsay Stead and Jamie Hartmann-Boye for their generous assistance throughout all stages of this review process.

### Characteristics of included studies [ordered by study ID]

**Burke 1992**

<table>
<thead>
<tr>
<th><strong>Methods</strong></th>
<th>Controlled cluster trial, no randomization reported. Public schools assigned to intervention in two communities, with the third community acting as control</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Participants</strong></td>
<td>Country: USA (3 communities in Iowa). 7th graders in participating schools. 1187 students in total completed baseline surveys. Authors reported majority were white (&gt; 90%), working or middle class students</td>
</tr>
<tr>
<td><strong>Interventions</strong></td>
<td>2 intervention communities received an education programme (6 sessions) plus competitions. 2 competitions ran concurrently: one which aimed to improve knowledge and the other to reward non-smoking&lt;br&gt;Competition 1: A t-shirt with the project logo was given to all students in the class at each school with most improved knowledge&lt;br&gt;Competition 2: Non-smoking competition between 7th graders in the two intervention communities. Students in the community with lower smoking rates at end of the project rewarded with a movie pass and voucher for free ice-cream&lt;br&gt;Control community received only education programme.</td>
</tr>
<tr>
<td><strong>Outcomes</strong></td>
<td>Baseline (Fall 1984) - survey of tobacco use (self-reported description using 5 categories, frequency measured using 5 categories, quantity measured using 6 categories), smoking beliefs, subjective norms, knowledge, saliva TCN&lt;br&gt;18 month follow-up (Spring 1986) - 18 month follow-up survey of tobacco use (self-reported description measured using 5 categories, smoking frequency using 10 categories [never smoked (1) to smoke more than half a packet a day (10)], smoking beliefs, subjective norms, saliva TCN&lt;br&gt;TCN results only used to justify the use of self-report except at baseline when 39 self-reported 'never smokers' were reclassified as 'occasional smokers.'</td>
</tr>
<tr>
<td><strong>Notes</strong></td>
<td>Theoretical basis: Intervention based on Fishbein &amp; Ajzen’s theory of reasoned action which posits that preventing behaviour depends on altering relevant beliefs &amp; norms</td>
</tr>

<table>
<thead>
<tr>
<th>Section</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Methods</td>
<td>Randomized controlled cluster trial</td>
</tr>
<tr>
<td>Participants</td>
<td>Country: Netherlands. 26 schools providing lower secondary education. Schools recruited through community health services. 14 of 54 health services provided names of schools. 26 schools were recruited but unclear about number of schools approached. ’First grade students’ from 154 classes participated (mean age 13 years). 1444 in intervention, 1118 in control at baseline. Minority of the sample were of non-Dutch ethnicity.</td>
</tr>
<tr>
<td>Interventions</td>
<td>As well as usual drug prevention/education programme, the intervention classes received three lessons on knowledge, attitude and social influence, followed by class agreement not to start smoking or stop smoking for 5 months. Admission to competition to win a prize dependent on classes completing registration, having &lt; 10% smokers after 5 months and producing a photo expressing the idea of a non-smoking class. Competition prizes (monetary prizes EURO220 - EURO450) available to 6 classes with &lt; 10% smoking and 'a photo best expressing a non-smoking class'. Control classes received the usual drug prevention/education programme; in 7 schools this was the national drug education programme.</td>
</tr>
</tbody>
</table>
### Outcomes

<table>
<thead>
<tr>
<th>Time Points</th>
<th>Self-reported smoking behaviour, intentions and attitudes measured at each time point. Smoking defined as including ‘experimenting’, weekly and daily smoking. No biochemical verification of smoking</th>

**Isensee 2012a**

**Methods**
Randomized controlled cluster trial

**Participants**
Country: Germany (one rural region). 7th grades of 212 eligible ‘Gymnasium’ (for high academic achieving students) and ‘Sekundarschule’ schools invited to participate. Schools stratified by type of school. Exclusion criteria: (a) foreseen closure of school in proceeding 2 years; (b) school engaged in tobacco control programme; (c) participated in the intervention before. 50% female. Mean age 12.65 years. SES measured using type of school as a proxy (Sekundarschule schools=lower SES). SES not reported. > 95% students were of German nationality

**Interventions**
Intervention: SFC competition: classes agree and sign a contract to remain smoke free for 6 months to enter a lottery to win a number of prizes, the grand prize including a class trip. Requirements to participate: at least 90% of class must agree to participate; classes monitor smoking on a weekly basis; classes report whether > 90% non-smokers to the organisers on a monthly basis. If the class is smoke free (> 90% non-smokers) they remain in the competition for prizes, with the main prize being a class trip; if not they drop out. The intervention group consisted of two subgroups: the classes who agreed to participate (IG-participation) and the classes who were randomized to intervention group but declined to participate (IG-no participation). Participating classes also received material including the contract, feedback cards, parent leaflet, CD-ROM, and access to web page

Control group classes received ‘usual curriculum.’

**Outcomes**
Baseline (October 2008)
1st follow-up at 7 months post baseline
2nd follow-up at 12 months post baseline
3rd follow-up at 19 months post baseline

At baseline and follow-ups participants completed a questionnaire asking about self-reported ‘current smoking’ (non-smoker, occasional use or regular use) and ‘lifetime smoking’ (never, experimenters, established smoking)

**Notes**
Theoretical basis: Intervention based on principles of correcting social norms (i.e. correcting the common overestimation of smokers by adolescents) and fostering commitment to a social contract

**Risk of bias**

### Schulze 2006

<table>
<thead>
<tr>
<th>Component</th>
<th>Details</th>
</tr>
</thead>
<tbody>
<tr>
<td>Methods</td>
<td>Randomized controlled cluster trial</td>
</tr>
<tr>
<td>Participants</td>
<td>Country: Germany (3 counties). 7&lt;sup&gt;th&lt;/sup&gt; grades of all Heidelberg schools and a random sample of schools in Mannheim and Rhine-Neckar counties. Schools stratified by type of school (unclear what the differences were between schools). 172 classes from 68 schools participated. Approximately 50% female. &gt; 90% 12 - 13 years. SES and ethnicity not reported</td>
</tr>
<tr>
<td>Interventions</td>
<td>Intervention: SFC competition. Classes agree and sign a contract to remain smoke free for 6 months to enter a lottery to win a number of prizes, the grand prize including a class trip. Requirements to participate: school classes decide to be a non-smoking class for 6 months; classes monitor smoking and report it regularly to competition organizers. If the class is smoke free (≥ 90% non-smokers) they remain in the competition for prizes. If &gt; 10% of the class is smoking, the class drops out of the competition. The intervention included weekly curricula consisting of health information about smoking and strategies for how to quit smoking and resist peer pressure to smoke. Unclear exactly what the control group received.</td>
</tr>
</tbody>
</table>
## Outcomes

Baseline (October 2008)
Follow-up at 24 months post baseline

At both baseline and follow-up participants completed a questionnaire asking about self-reported smoking. Note additional response options added in follow-up survey

### Notes

Theoretical basis: None reported

## Risk of bias

<table>
<thead>
<tr>
<th>Methods</th>
<th>Controlled cluster trial</th>
</tr>
</thead>
<tbody>
<tr>
<td>Participants</td>
<td>Country: Finland. Intervention: All 600 junior high schools in Finland were invited to be in SFC competition each year. In 1991-2, 1219 8th Grade classes (from 368 schools) entered the competition (1/3 of age cohort) and 65 of these classes were randomly selected to take part in this study. Control group: randomly selected from classes that did not register for the competition. Age of participants not provided but reported they were 8th graders (approx. 14 year olds). Sex, SES and ethnicity not reported.</td>
</tr>
<tr>
<td>Interventions</td>
<td>Intervention: SFC competition (here known as 'no smoking class competition'): classes agree and must remain 100% smoke free for 6 months to enter a lottery to win 4 main prizes of US$2000 and 10 second prizes of US$200; the grand prize including a class trip. Prize money can be used in any way the class chooses. Requirements to participate: All of class must agree to participate; classes monitor smoking on a weekly basis, if anyone starts smoking and does not quit the class must drop out of the competition. The contact teacher for each class organises health education sessions about smoking during school hours - no other details provided about this education. Unclear what control group classes received.</td>
</tr>
<tr>
<td>Outcomes</td>
<td>Baseline (Fall 1991) 1st follow-up at 6 months post baseline (Spring 1992) 2nd follow-up at 18 months post baseline (Spring 1993) At both baseline and follow-up participants completed a questionnaire asking about self-reported daily smoking (Do you now smoke?: not at all/less than once a month/ 1 - 2 times a month/ 1 - 2 times a week/daily). Daily smokers were reported as smokers.</td>
</tr>
<tr>
<td>Notes</td>
<td>Theoretical basis: not provided</td>
</tr>

### Wiborg 2002

<table>
<thead>
<tr>
<th>Methods</th>
<th>Controlled cluster trial</th>
</tr>
</thead>
<tbody>
<tr>
<td>Participants</td>
<td>Country: Germany (three cities). Intervention: multiple secondary school classes from schools who registered for the SFC competition (all schools were invited) from Hamburg and Berlin. The intervention group consisted of classes that decided to participate in the competition. Control: The same proportion of classes from different grades and school types as in the intervention group was randomly selected from classes in Hanover that had not been invited to participate in the competition. Mean age 12.9 years, similar number boys and girls. SES and ethnicity not reported</td>
</tr>
<tr>
<td>Interventions</td>
<td>Intervention: SFC competition: classes agree and sign a contract to remain smoke free for 6 months to enter a lottery to win a number of prizes, the grand prize including a class trip. Requirements to participate: At least 90% of class must agree to participate, classes monitor smoking on a weekly basis, classes report whether &gt; 90% non-smokers to the organisers on a monthly bases. If the class is smoke free (&gt; 90% non-smokers) they remain in the competition for prizes, with the main prize being a class trip; if not they drop out. The intervention group consisted of two subgroups: the classes who successfully ended the competition and the classes who dropped out of the competition (but continued in the study). Participating classes also received two newsletters with information about competition, teachers received a brochure</td>
</tr>
<tr>
<td>Outcomes</td>
<td>Baseline (October/November 1998)</td>
</tr>
<tr>
<td></td>
<td>1st follow-up at 6 months post baseline (May 1999)</td>
</tr>
<tr>
<td></td>
<td>2nd follow-up at 12 months post baseline (November 1999)</td>
</tr>
<tr>
<td></td>
<td>At both baseline and follow-up participants completed a questionnaire asking about self-reported 'four week smoking prevalence' ('Have you smoked during the last four weeks?') and 'daily smoking prevalence' ('Have you smoked daily during the last seven days?')</td>
</tr>
<tr>
<td>Notes</td>
<td>Theoretical basis: Reference to learning theory that asserts that positive reinforcement enhances the probability of producing a desired behaviour</td>
</tr>

Appendix 6. CSA search strategy

This strategy was used for ASSIA, ERIC, Sociological Abstracts and PAIS
(Keyword includes title, abstract and descriptors)
KW=(Incentive* or competition* or contest* or lotter* or raffle* or reward* or prize* or voucher* or gift* or inducement* or ‘contingent payment’ or ‘deposit contract’ or reinforcement or punishment)) and (KW=(smok* or tobacco or cigarette*)) and (KW=(adolescent* or minor or minors or child* or juvenile* or girl* or boy* or teen* or adolescent* or youth or young people))

HISTORY
Protocol first published: Issue 8, 2010
Review first published: Issue 10, 2012

CONTRIBUTIONS OF AUTHORS
Vanessa Johnston developed the search strategies, undertook the initial screening of retrieved records, extracted data from the eligible studies and, together with David Thomas, assessed the quality of the studies and risk of bias of the included studies. Vanessa Johnston completed the first draft of this review. David Thomas conceived of this review, completed data extraction for the eligible studies and, together with Vanessa Johnston, assessed the quality of the studies and risk of bias of the included studies. Selma Liberato performed the reanalyses of data for this review and the meta-analysis and assisted with the development of this review. David Thomas and Selma Liberato provided critical comment and revision of the draft manuscript.
